PTPN2, a candidate gene for type 1 diabetes, modulates interferon-gamma-induced pancreatic beta-cell apoptosis

Running title: PTPN2 regulates cytokine-induced β-cell death.

**Objective:** The pathogenesis of type 1 diabetes has a strong genetic component. Genome-wide association scans recently identified novel susceptibility genes including the phosphatases PTPN22 and PTPN2. We hypothesized that PTPN2 plays a direct role in β-cell demise and assessed PTPN2 expression in human islets and rat primary and clonal β-cells, besides evaluating its role in cytokine-induced signaling and β-cell apoptosis.

**Research design and methods:** PTPN2 mRNA and protein expression was evaluated by real time PCR and Western blot. Small interfering (si)RNAs were used to inhibit the expression of PTPN2 and downstream STAT1 in β-cells, allowing the assessment of cell death after cytokine treatment.

**Results:** PTPN2 mRNA and protein are expressed in human islets and rat β-cells, and up-regulated by cytokines. Transfection with PTPN2 siRNAs inhibited basal and cytokine-induced PTPN2 expression in rat β-cells and dispersed human islets cells. Decreased PTPN2 expression exacerbated IL-1β + IFN-γ-induced β-cell apoptosis, and turned IFN-γ alone into a pro-apoptotic signal. Inhibition of PTPN2 amplified IFN-γ-induced STAT1 phosphorylation while double knockdown of both PTPN2 and STAT1 protected β-cells against cytokine-induced apoptosis, suggesting that STAT1 hyperactivation is responsible for the aggravation of cytokine-induced β-cell death in PTPN2-deficient cells.

**Conclusions:** We identified a functional role for the type 1 diabetes candidate gene PTPN2 in modulating IFN-γ signal transduction at the β-cell level. PTPN2 regulates cytokine-induced apoptosis and may thereby contribute to the pathogenesis of type 1 diabetes.
Type 1 diabetes (T1D) is a chronic autoimmune disease with a strong genetic etiology. Genetic predisposition to T1D depends on a small number of genes having large effects and a larger number of genes having small effects (1). These genes interact with putative environmental factors, which may include viral infections, triggering insulitis and eventually diabetes (2). Recent genome-wide association studies have shown association between T1D and four chromosome regions, pointing to several new candidate genes for the disease (3). Most of the newly and previously identified genes are assumed to regulate immune function. This contrasts with T2D, where similar studies indicate a major role for genes regulating β-cell function (4).

We have presently evaluated whether the recently identified candidate genes for T1D (3;5) are expressed in pancreatic β-cells and whether their expression is modulated by pro-inflammatory cytokines. This was done by examining our previous array analyses of cytokine-treated or virus-infected rodent and human β-cells/pancreatic islets (6-10; complete information on these arrays is available at the Beta Cell Gene Expression Bank; 11), and new array analyses performed in our laboratory using the new Affymetrix rat array Genechip 230.2.0 (unpublished data). This analysis identified β-cell expression of the candidate gene Protein Tyrosine Phosphatase (PTP)N2.

PTPN2 (also known as TC-PTP or PTP-S2) is a member of the first nontransmembrane (NT1) subfamily of PTPs. PTPs are a superfamily of enzymes with opposite roles as compared to Protein Tyrosine Kinases (12). PTPN2 is expressed in immune cells and its expression is modulated by cell cycle, mitogenic agents and cytokines (13). PTPN2 exists as 2 isoforms generated from alternative splicing: a major TC45 isoform (45 kD) containing a nuclear localization sequence and that shuttles between the nucleus and the cytoplasm, and a less abundant TC48 isoform (48 kD) that is anchored to the endoplasmic reticulum (ER) (13). Many targets have already been identified for TC45, including Janus kinases (JAKs) and signal transducer and activator of transcription (STATs), p42/44 MAPK (ERK), Epidermal Growth Factor Receptor (EGFR) and Insulin receptor β (IRβ) (14-17). Several of these pathways have been implicated in the control of β-cell physiology, survival and expansion (18-20).

We have previously suggested that islet inflammation and subsequent β-cell death develops in the context of a “dialogue” between the immune system and β-cells (21). Thus, β-cells exposed to viral agents (6;22), or to endogenous Toll Like Receptors ligands (23), release cytokines and chemokines that attract and activate macrophages, T cells and B cells. These immune cells will then trigger β-cell apoptosis via contact mediators such as Fas-FasL and/or via secretion of pro-inflammatory cytokines such as interferon(IFN)-γ, interleukin(IL)-1β and tumor necrosis factor(TNF)-α (21;24). IFN-γ has a key role in this process. Thus, neither IL-1β nor TNF-α alone induce human or rodent β-cell death, but combinations of these cytokines with IFN-γ lead to 50% β-cell death after 6-9 days (21;24). IFN-γ signal transduction involves activation of the tyrosine kinases JAK1 and JAK2, that phosphorylate STAT1 which then dimerizes and translocates to the nucleus where it binds γ-activated sites of diverse genes (21). Excessive activation of JAK/STAT signaling may lead to cell death, and STAT1 transcriptional activity is regulated by multiple negative feedback mechanisms, including inhibition of JAKs by specific phosphatases and by the suppressors of cytokine signaling (SOCS), and inhibition of STAT1 activity by Protein Inhibitor of
Activated STAT (PIAS) proteins (25). β-cells from STAT1-deficient mice (STAT1−/−) are protected against IL-1β + IFN-γ-induced apoptosis, and STAT1−/− mice are more resistant to diabetes induced by multiple low doses of streptozotocin (MLDS) or following backcross into NOD mice (18;26). This protective effect takes place at the β-cell level since islets from STAT1−/−, but not from wild type mice, prevent diabetes when transplanted into wild type mice subsequently treated with MLDS (27). However, it still remains unclear whether modulation of phosphatases modifies IFN-γ-induced β-cell apoptosis.

We presently report that PTPN2 is regulated by the cytokines IL-1β, IFN-γ and TNF-α in rodent and human pancreatic islet cells. Importantly, small interfering (si)RNA-mediated PTPN2 knockdown increases STAT1 activation, and aggravates cytokine-induced β-cell apoptosis in a STAT1-dependent manner. These observations indicate that one of the new candidate genes for T1D may act at the immune and at the β-cell level, exacerbating cytokine-induced β-cell apoptosis under inflammatory conditions.

RESEARCH DESIGN AND METHODS

Culture of primary FACS-sorted rat β-cells, human islets and INS-1E cells: Male Wistar rats (Charles River Laboratories, Brussels, Belgium) were housed and used according to the guidelines of the Belgian Regulations for Animal Care. Islets were isolated by collagenase digestion and hand picked under a stereomicroscope. β-cells were purified by autofluorescence-activated cell sorting (FACS Aria, BD Bioscience, San Jose, CA, USA) (28;29). The preparations contained 90.4 ± 3.2% β-cells (n=4). β-cells were cultured for 2 days in Ham’s F-10 medium containing 10 mM glucose, 2 mM glutamAX, 50 μM 3-isobutyl-1-methylxanthine, 5% FBS, 0.5% charcoal-absorbed BSA (Boehringer, Indianapolis, IN, USA), 50 U/ml penicillin and 50 μg/ml streptomycin (29;30). During cytokine exposure, cells were cultured in the same medium but without serum.

Human islets were isolated from 11 non-diabetic organ donors (age 63 ± 5 years; body mass index 25.1 ± 0.8 kg/m²) in Pisa, Italy, with the approval of the local Ethics Committee. Islets were isolated by enzymatic digestion and density-gradient purification (31), and cultured in M199 medium containing 5.5 mM glucose. Their functional status was determined using glucose-stimulated insulin release and was 2.8 ± 0.4 (expressed as stimulation index). The human islets were shipped to Brussels within 1-5 days of isolation. After overnight recovery in Ham’s F-10 containing 6.1 mM glucose, 10% FBS, 2 mM GlutaMAX, 50 μM 3-isobutyl-1-methylxanthine, 1% BSA, 50 U/ml penicillin and 50 μg/ml streptomycin, islets were exposed to cytokines in the same medium without FBS for 2 days. The percentage of β-cells, examined in the 11 dispersed islet preparations by staining with anti-insulin antibody (1:1000, Sigma, Bornem, Belgium) and donkey anti-mouse IgG rhodamine (1:200, Lucron Bioproducts, De Pinte, Belgium), was 49 ± 5%.

The rat insulin-producing INS-1E cell line (a kind gift from Dr. C. Wollheim, Centre Medical Universitaire, Geneva, Switzerland) was cultured as previously described (32;33).

RNA interference: The siRNAs used in this study are listed in Supplementary Table A1 (available in the online appendix at http://diabetes.diabetesjournals.org). The best settings for the transfection of siRNAs in INS-1E cells, primary FACS-sorted rat β-cells and dispersed human islets were established by using a FITC-conjugated siRNA (siGLO Green Transfection Indicator – Thermo Scientific). Different transfection methods were tested, including electroporation and several lipid reagents. Among those, DharmaFECT 1 (Thermo Scientific) was selected for its high transfection efficiency, namely 95 ± 2.7% in INS-1E cells and 80.7 ±
PTPN2 regulates cytokine-induced β-cell death

5.6% in primary rat β-cells. No cell toxicity was observed with this transfection method (% cell death: 9.4 ± 1.7% after transfection vs 8.4 ± 2.2% in control for INS-1E cells and 9.8 ± 1.3% after transfection vs 7.4 ± 1.7% in control for primary rat β-cells). Cells were cultured in antibiotic-free medium for at least 24h before transfection. For transfection, the siRNA and the DharmaFECT were diluted separately in OptiMEM medium, and incubated at RT for 5 minutes. Lipid-siRNA complexes were then formed at RT for 20 minutes in a proportion of 0.75, 1.25 µl and 1.75 µl of DharmaFECT to 150 nM of siRNA for INS-1E cells, primary β-cells and dispersed human islets respectively. The complexes were diluted 5 times in antibiotic-free medium and added to the cells at a final concentration of 30 nM siRNA (except when indicated otherwise) for overnight transfection. The concentration of 30 nM was selected after dose-response studies (data not shown). Afterwards, cells were cultured for a 48-hour recovery period and subsequently exposed to cytokines.

**Cell treatment and NO measurement:** The following cytokine concentrations were used, based on previous dose–response experiments (10;24;33): recombinant human IL-1β (specific activity (SA) 1.8x10^7 U/mg; a kind gift from C. W. Reinolds, National Cancer Institute, Bethesda, MD, USA) at 10, 50 or 100 U/ml as indicated; recombinant murine TNF-α (SA: 2x10^8 U/mg; Innogenetics, Gent, Belgium) at 1,000 U/ml; recombinant rat and human IFN-γ (SA: 2x10^7 U/mg; R&D Systems, Abingdon, UK) at 100 and 1000 U/ml for rat cells and human islets respectively. When cells were treated with cytokines, culture supernatants were collected for nitrite determination (nitrite is a stable product of NO oxidation) at OD540nm using the Griess method (34). Palmitate (sodium salt, Sigma) was dissolved in DMSO and used at a concentration of 25 µM.

**Assessment of cell viability:** The percentage of viable, apoptotic and necrotic cells was determined following a 15 minute incubation with the DNA-binding dyes Propidium Iodide (PI, 5 µg/ml, Sigma) and Hoechst 33342 (HO, 5 µg/ml, Sigma) (10;29;36). A minimum of 500 cells was counted in each experimental condition. Viability was evaluated by two independent observers, one of them being unaware of sample identity. The agreement between findings obtained by the two observers was > 90%. Results are expressed as percent apoptosis, calculated as number of apoptotic cells / total number of cells x 100. In some experiments apoptosis was confirmed using the Cell Death Detection ELISApplus kit (Roche Diagnostics, Vilvoorde, Belgium) which detects cytoplasmic fragmented DNA.

**mRNA extraction and real time PCR:** Poly(A)^+ mRNA was isolated from INS-1E cells, rat primary β-cells and human islets using the Dynabeads mRNA DIRECT™ kit (Invitrogen), and reverse transcribed as previously described (10;29;37). The real time PCR amplification reaction was done as described (29;37), using SYBR Green and compared to a standard curve (38). Expression values were corrected for the housekeeping gene glyceraldehyde-3-phosphate dehydrogenase (GAPDH). IL-1β alone does not modify GAPDH expression while exposure to IL-1β + IFN-γ reduces its expression according to cell death in INS-1E cells (Supplementary Fig. A1 and 7;10). The primers used in this study are detailed in Supplementary Table A2 (online appendix).

**Western blot analysis:** Cells were washed with cold PBS and lysed with either Laemmli buffer or Phospho lysis buffer (the compositions of the buffers are provided in Supplementary Table A3 – online appendix). Lysates were then resolved by 8-10% SDS-PAGE and transferred to a nitrocellulose membrane. The antibodies used in this study
PTPN2 regulates cytokine-induced β-cell death

are listed in Supplementary Table A4 – online appendix. Immunoreactive bands were revealed using the SuperSignal West Femto chemiluminescent substrate (Thermo Scientific), detected using a LAS-3000 CCD camera and quantified with the Aida Analysis software (Fujifilm).

**Immunofluorescence:** INS-1E cells were seeded onto glass coverslips and treated as indicated. Cells were washed with cold PBS, fixed for 10 min in 100% methanol at -20°C, washed three times with PBS, quenched 5 min in PBS/0.1% sodium borohydride, washed twice with PBS and incubated for 5 min in PBS containing 0.2% Triton X-100 (PBST). Following a 1h blocking with 5% normal goat serum (NGS) in PBST, cells were incubated overnight with PTPN2 antibodies (0.7 µg/ml) in PBST/0.5% NGS (Supplementary Table A4). Cells were washed three times with PBST and FITC-conjugated goat anti-mouse antibodies (Lucron Bioproducts) were applied for 2h at 1:200 in PBST. After 2 washes with PBST, nuclei were counterstained with Hoechst 33342 (HO) for 5 min, and washed 3 times with PBS. Coverslips were mounted in mounting medium (Dakocytomation), and immunofluorescence was visualized on a Zeiss microscope.

**Statistical analysis:** Data are presented as mean ± SEM. Comparisons were performed by two-tailed paired Student’s t-test or by ANOVA followed by Student’s t test with Bonferroni correction. A p value <0.05 was considered statistically significant.

**RESULTS**

**Cytokines up-regulate PTPN2 mRNA and protein expression in primary rat β-cells, human islets and INS-1E cells:** We first evaluated the expression of PTPN2 mRNA (both TC45 and TC48 isoforms) in primary FACS-sorted rat β-cells, human islets and rat insulin-producing INS-1E cells, and tested whether cytokine treatment would affect its expression. PTPN2 mRNA was expressed in untreated primary rat β-cells and human islets cells, and IL-1β + IFN-γ exposure up-regulated its expression by 9.6-fold (rat β-cells) and 2.2-fold (human islets) after respectively 24 and 48h (Figs. 1A and 1B). A time course of IL-1β + IFN-γ treatment in INS-1E cells indicated that PTPN2 mRNA was already induced after 2h, increasing progressively up to 24h (Fig. 1C). We then confirmed by Western blot that PTPN2 was upregulated by respectively 2 and 3 folds in human islets and INS-1E cells after IL-1β + IFN-γ treatment (Figs. 1D and 1E and Fig. 3B and 3C). In accordance with previous reports (13), we observed TC45 (arrow, Fig. 1D and 3B) to be the major PTPN2 isoform expressed in β-cells, with TC48 being poorly expressed (Figs. 1D and 3B). In contrast, the expression of PTPN22 (another phosphatase associated with T1D risk; 39) was only present in samples from rat spleen and lymph nodes (used as positive controls), whereas no or marginal PTPN22 expression was observed in primary β-cells, human islets and INS-1E cells. The expression of PTPN22 was not modified by cytokines (Supplementary Fig. A2 – online appendix).

**PTPN2 subcellular distribution:**

PTPN2 was mainly located in the nucleus under unstimulated conditions (Fig. 2 – left panels). However, a 15 minute treatment with IFN-γ alone or in combination with IL-1β or TNF-α resulted in redistribution of the protein between the cytoplasm and the nucleus (Fig. 2 – middle and right panels).

**siRNA targeting PTPN2 inhibits basal and cytokine-induced PTPN2 expression, and exacerbates cytokine-induced apoptosis in INS-1E cells, primary rat β-cells and dispersed human islets:** We next examined the role of PTPN2 in β-cells. To this end, INS-1E cells were left untransfected, transfected with an irrelevant control siRNA (siCtrl), or with an siRNA targeting both PTPN2 isoforms (siPTPN2). Cells were then left untreated, or treated for
PTPN2 regulates cytokine-induced β-cell death

24h with IL-1β, IFN-γ, TNF-α or with the combination of IL-1β + IFN-γ or TNF-α + IFN-γ. PTPN2 mRNA expression was significantly up-regulated after IL-1β and IL-1β + IFN-γ treatment in untransfected and siCtrl-transfected INS-1E cells (Fig. 3A). The expression of PTPN2 proteins was increased by all cytokines tested, alone or in combination, in both untransfected and siCtrl-transfected cells (Fig. 3B and 3C), suggesting that PTPN2 expression is regulated at both transcriptional and post-transcriptional levels. Transfection with PTPN2 siRNA potently inhibited basal and cytokine-induced PTPN2 expression at the mRNA and protein level (Fig. 3A-C). We then evaluated whether siRNA-mediated PTPN2 inhibition affects cytokine-induced apoptosis in INS-1E cells. As expected, a 24h treatment with IL-1β + IFN-γ or TNF-α + IFN-γ induced apoptosis in untransfected and siCtrl-transfected cells, whereas each individual cytokine did not (Fig. 4A; of note, the necrotic component was <2% under all experimental conditions tested; data not shown). The inhibition of PTPN2 exacerbated β-cell apoptosis after exposure to both IL-1β + IFN-γ and TNF-α + IFN-γ treatments. Importantly, PTPN2 inhibition also rendered IFN-γ treatment toxic to the cells, while this cytokine alone failed to induce apoptosis in both control counterparts (Fig. 4A). These results were confirmed using a second method to evaluate apoptosis, namely quantification of cytoplasmic fragmented DNA (Fig. 4B), and also with a second siRNA targeting PTPN2 (see below). The increased apoptosis in cytokine-treated PTPN2-deficient INS-1E was not accompanied by a more severe decrease in Ins1 and Ins2 mRNA contents in these cells (Supplementary Fig. A3 – online appendix), and could not be explained by a higher release of nitric oxide (NO), since nitrite was similarly produced by untransfected, siCtrl- and siPTPN2-transfected cells after IL-1β, IL-1β + IFN-γ and TNF-α + IFN-γ treatments (Fig. 4C). Blocking PTPN2 using siRNA also augmented IFN-γ-, IL-1β + IFN-γ- and TNF-α + IFN-γ-induced apoptosis in primary rat β-cells (Fig. 4D). Similar observations were made in dispersed human islet cells, in which siRNA-mediated PTPN2 inhibition exacerbated IL-1β + IFN-γ-induced cell death by 30-38% (Fig. 4E and F). This was again independent of NO production (data not shown). This effect seems to be specific for cytokines, since PTPN2 inhibition did not increase β-cells apoptosis in response to palmitate, high glucose or to the SERCA blocker CPA (Supplementary Fig. A4).

PTPN2 inhibition increases IFN-γ-induced STAT1 and STAT3 phosphorylation: Taking into account that STAT1 is a substrate of PTPN2 in other cell types (13) and that it is an important mediator of cytokine-induced β-cell apoptosis (18), we next examined the effect of PTPN2 inhibition on the kinetics and magnitude of IFN-γ-induced STAT1 phosphorylation. STAT1 phosphorylation was highly induced after 15 minutes of IFN-γ treatment in both untransfected and siCtrl-transfected controls, slowly decreasing between 2h and 24h (Fig. 5A and 5B). However, IFN-γ-induced STAT1 phosphorylation was markedly enhanced in cells lacking PTPN2, reaching a peak at 1 to 2h and slowly decreasing afterward (Fig. 5A and 5B). We confirmed that the increased STAT1 phosphorylation in PTPN2-deficient cells was not due to an augmentation of total STAT1 content in these cells (Fig. 5A). Comparable results were observed for STAT3, another target of PTPN2 phosphatase activity, with clearly increased STAT3 phosphorylation in PTPN2-deficient cells (Fig. 5A and 5C). These data demonstrate that the phosphatase PTPN2 is a major modulator of IFN-γ-induced STAT1 and STAT3 activity in β-cells. We also evaluated the p42/44 MAPK (ERK), EGFR and insulin receptor β (IRβ) activation pathways, previously described as PTPN2 targets in other cell types.
PTPN2 regulates cytokine-induced β-cell death

Neither ERK nor EGFR signalling pathways were affected after PTPN2 inhibition in INS-1E cells (Supplementary Fig. A5). On the other hand, there was an increase in IRβ phosphorylation after 30 minutes of cytokine treatment in PTPN2-inhibited INS-1E cells that lasted until 14h (Supplementary Fig. A5).

Double knockdown of PTPN2 and STAT1 protects INS-1E cells against cytokine-induced apoptosis: In order to evaluate the role of STAT1 in the exacerbation of cytokine-induced β-cell apoptosis observed after PTPN2 inhibition, we additionally interfered with STAT1 in a double knockdown approach. We first confirmed by Western blot that both PTPN2 and STAT1 siRNAs adequately inhibited their respective targets without affecting the expression of the other protein, and also that the double transfection of PTPN2 and STAT1 siRNAs potently inhibited both target proteins (Fig. 6A). As previously shown (Fig. 4), IL-1β + IFN-γ or TNF-α + IFN-γ induced apoptosis to a similar degree in both control conditions, and PTPN2 inhibition exacerbated cytokine-induced apoptosis, also rendering treatment with IFN-γ alone toxic to the cells (Fig. 6B). Inhibition of STAT1 protected the cells against IL-1β + IFN-γ- and TNF-α + IFN-γ-induced apoptosis (by 56% and 67% respectively). STAT1 knockdown abrogated the proapoptotic effect of PTPN2 inhibition in cells exposed to IFN-γ or to combinations of cytokines (Fig. 6B). These results were confirmed using a second siRNA targeting PTPN2 expression (Supplementary Fig. A6 – online appendix), and suggest that increased STAT1 activity contributes to the aggravation of cytokine-induced apoptosis in PTPN2-deficient β-cells.

DISCUSSION

We presently show that the phosphatase PTPN2 is expressed in human islets and rat primary and immortal β-cells, and that its expression is regulated by the pro-inflammatory cytokines IL-1β, IFN-γ and TNF-α in these cells. PTPN2 was first identified in humans as a T cell PTP (41) with two spliced variants, namely TC45 and TC48 (13;42). In rat β-cells and human islets the TC45 isoform is by far the most prevalent (Fig. 1D and 3B), and it is able to shuttle between the nucleus and the cytoplasm following cytokine exposure (Fig. 2). This change in subcellular location of PTPN2 has been shown previously in other cell types (14;16), and allow the phosphatase to target numerous cellular substrates, including cytoplasmic JAK tyrosine kinases, EGFR, the IR β and nuclear STAT1, STAT3, STAT5 and STAT6 (43;44). Due to its modulatory role in a wide variety of signaling pathways, perturbations in PTPN2 expression are associated with diverse pathogenic processes, including ABC-like Diffuse Large B-Cell Lymphomas (45), inflammation-associated tumorigenesis (44) and several autoimmune disorders (see below).

PTPN2 inhibition in β-cells results in an early and more intense STAT1 and STAT3 activation after IFN-γ treatment, suggesting that this phosphatase plays an important role in the dephosphorylation and consequent inactivation of these transcription factors in β-cells. This early regulation of IFN-γ-induced STAT1 activation seems to be critical for the subsequent triggering of β-cell apoptosis, since PTPN2-deficient β-cells show an aggravation of cytokine-induced apoptosis which is reverted by the combined inhibition of PTPN2 and STAT1. Importantly, PTPN2 inhibition unmasked the pro-apoptotic effect of IFN-γ alone in both INS-1E and primary β-cells, while it failed to augment palmitate- or CPA-induced β-cell death. Taken together, these observations indicate two interesting aspects that require additional investigation: 1. the crucial negative feedback of PTPN2 on the STAT1 signaling pathway suggest that PTPN2 is part of the “defense mechanisms” triggered by β-cells in response to cytokines.
It remains to be clarified why this, and other defense mechanisms (24), are not sufficient to protect β-cells against apoptosis; 2. IFN-γ alone induces STAT1 activation, but this only leads to apoptosis when PTPN2 activation is prevented. This suggests that STAT1 must cross a “nuclear activation threshold” before becoming pro-apoptotic to β-cells. It remains to be clarified whether this threshold depends on the intensity/length and/or periodicity of STAT1 activation, as previously suggested for NF-κB (33).

The exacerbation of apoptosis in β-cell with decreased PTPN2 expression is independent of augmented nitric oxide production. This contrasts with observations reporting that PTPN2-deficient macrophages produce higher amounts of nitric oxide under inflammatory conditions (40;46), highlighting the differential regulation of inflammation-associated genes in cells from different backgrounds.

As discussed above, the transcription factor STAT1 has a major role in cytokine-induced β-cell apoptosis in vitro (18) and in vivo (27). It is thus conceivable that a genetically-determined modification in the expression and/or the function of PTPN2 may sensitize β-cells to INF-γ/STAT1-driven pro-apoptotic signaling, amplifying β-cell loss under inflammatory conditions, and in some cases, contributing to diabetes. The potential effect of the transient hyper-phosphorylation of STAT3 or IRβ in PTPN2-inhibited cells remains to be clarified. STAT3 has been reported to be dispensable for β-cell development and function (47), but it is generally associated with increased survival of tumoral cells (48), while the IR may exert a positive feedback on β-cell function and survival (20).

Over the past few years, several new candidate genes have been identified in human T1D. Most of these genes are expressed in the immune system, including Major Histocompatibility Complex (MHC - e.g. HLA-DRB1), CTLA4, IL-2Rα (CD25), IFIH1 (MDA5), and several protein tyrosine phosphatases, namely PTPN22, PTPN11 and the recently reported PTPN2 (3;49). Modified function or regulation of these genes could contribute to the development of an autoimmune response. Thus, nonsynonymous single nucleotide polymorphisms (SNPs) in PTPN22 (human LYP), have been associated with T1D and other autoimmune processes, probably secondary to defective deletion of autoreactive T cells during thymic selection (39). The fact that PTPN22 is not expressed in β-cells (present data) reinforces the likelihood that this is solely due to effects on the immune system. PTPN2-null mice present severe abnormalities in the immune system, resulting in a systemic inflammatory disease and widespread tissue infiltration by mononuclear cells (13;46;50). Moreover, the PTPN2 gene is associated with several other autoimmune disorders besides T1D, including Crohn’s disease, ulcerative colitis and rheumatoid arthritis (49;51;52). It is currently unknown whether the SNPs identified in the PTPN2 gene on chromosome 18p11 will lead to a gain- or a loss-of-function of the protein. PTPN2 overexpression in other cell types has been shown to induce a p53- and caspase 1-dependent apoptosis (53), while suppression of PTPN2 sensitize β-cells to cytokine-induced apoptosis (present data). In experiments on INS-1E cells, we observed that DNA vector-based overexpression of PTPN2 induced 30-50% of apoptosis 36h after transfection, whereas there was <8% apoptotic cells in control-tranfected cells (data not shown). These preliminary results require experimental confirmation in primary rat and human β-cells using adenoviral vectors to overexpress PTPN2, but they suggest that PTPN2 must be tightly regulated to avoid deleterious effects.

Pancreatic β-cells themselves may play an active role in the pathogenesis of T1D (21) and at least three of the T1D-associated genes are expressed in β-cells, namely insulin,
IFIH1 (MDA5) (6;54) and PTPN2 (present study). β-cells have been shown to participate actively in the recruitment and activation of the immune system by secreting various chemokines and cytokines under inflammatory conditions (18;21;55), and by providing “danger signals” to the immune system during apoptosis, especially in the context of local inflammation (56). We presently demonstrate that changes in PTPN2 function in β-cells sensitize these cells to surrounding pro-apoptotic inflammatory signals (e.g. cytokines), potentially amplifying β-cell loss and insulitis. This suggests that PTPN2, a T1D-associated gene, may modulate β-cell apoptosis in early T1D independently of its potential effects on the immune system.

PTPN2 regulates cytokine-induced β-cell death

FIGURE LEGENDS

Figure 1. Cytokines up-regulate PTPN2 expression in primary FACS-sorted rat β-cells, human islets and INS-1E cells.
(A) Rat β-cells were cultured for 2 days and subsequently left untreated or treated with the combination of IL-1β (10 U/ml) + IFN-γ (100 U/ml) for 24h; (B-D-E) Hand-picked human islets were cultured overnight, and then left untreated or exposed to IL-1β (50 U/ml) + IFN-γ (1000 U/ml) for 48h; (C) INS-1E cells were left untreated or treated with IL-1β (10 U/ml) + IFN-γ (100 U/ml) for 2, 6, and 24h as indicated. (A-C) PTPN2 mRNA expression was assayed by RT-PCR and normalized for the housekeeping gene GAPDH; (D) PTPN2 and α-tubulin expression in human islets were evaluated by Western blot. (E) Mean optical density measurements of PTPN2 Western blots corrected for protein loading by α-tubulin (representative figure in (D)). Results are mean ± SEM of 3-5 independent experiments; * p<0.05, ** p<0.01 and *** p<0.001 vs untreated cells by Student’s t test.

Figure 2. Effects of cytokine exposure on PTPN2 subcellular distribution.
INS-1E cells were plated onto glass coverslips and left untreated or treated for 15 min. with IFN-γ (100 U/ml), IL-1β (10 U/ml) + IFN-γ (100 U/ml) or TNF-α (1000 U/ml) + IFN-γ (100 U/ml). Cells were then fixed and processed for immunofluorescence as described in Methods. The figure is representative of 5 independent experiments.

Figure 3. A siRNA targeting PTPN2 inhibits basal and cytokine-induced PTPN2 expression in INS-1E cells.
INS-1E cells were left untransfected (NT - white bars) or transfected with 30 nM of either a control siRNA (siCtrl – hatched bars), or a pool of siRNAs targeting PTPN2 (siPTPN2 – black bars). After 2 days of recovery, cells were left untreated, or treated for 24h with IL-1β (100 U/ml), IFN-γ (100 U/ml), TNF-α (1000 U/ml), IL-1β (10 U/ml) + IFN-γ (100 U/ml) or TNF-α (1000 U/ml) + IFN-γ (100 U/ml). (A) PTPN2 mRNA expression was assayed by RT-PCR and normalized for the housekeeping gene GAPDH. Results are mean ± SEM of 4 independent experiments. (B) PTPN2 and α-tubulin protein expression were evaluated by Western blot. The results are representative of 5 independent experiments. (C) Mean optical density measurements of PTPN2 Western blots, corrected for protein loading by α-tubulin. Results are mean ± SEM of 5 independent experiments; a: p<0.001, b: p<0.01 and c: p<0.05 vs untreated NT or untreated transfected with the same siRNA; d: p<0.01 vs untreated NT & siCtrl; e: p<0.01 vs IL-1β-treated NT & siCtrl; f: p<0.01 vs IFN-γ-treated NT & siCtrl; g: p<0.01 vs TNF-α-treated NT & siCtrl; h: p<0.001 vs IL-1β + INF-γ-treated NT & siCtrl; i: p<0.01 vs TNF-α + INF-γ-treated NT & siCtrl; ANOVA followed by Student’s t test with Bonferroni correction.

Figure 4. siRNA-mediated PTPN2 inhibition exacerbates cytokine-induced apoptosis in INS-1E cells, primary rat β-cells and dispersed human islets, independently of nitric oxide production.
INS-1E were transfected and treated as described in Fig. 3. Apoptosis was evaluated after 24h using (A) HO/PI staining and (B) Cell Death Detection ELISAplus kit. (C) INS-1E were transfected and treated as described in Fig. 3. and nitrite concentrations in supernatants were measured as described in Methods (D) Primary FACS-sorted rat β-cells were cultured for 2 days and then transfected as described in Fig. 3. After 2 days of recovery, cells were left untreated or
PTPN2 regulates cytokine-induced β-cell death

treated for 72h with IFN-γ (100 U/ml), IL-1β (10 U/ml) + IFN-γ (100 U/ml) or TNF-α (1000 U/ml) + IFN-γ (100 U/ml). (E-F) Dispersed human islets were left untransfected, or transfected with 30 nM of siCtrl or human siPTPN2 #1 or #2 and cultured for a 48h recovery period. Cells were then treated with IL-1β (50 U/ml) + IFN-γ (1000 U/ml) for: (E) 48h when PTPN2 and α-tubulin were evaluated by Western blot; (F) 96h when apoptosis was evaluated by HO/PI staining. Results are mean ± SEM of 4 experiments; a: \( p < 0.001 \) and b: \( p < 0.05 \) vs untreated NT or untreated transfected with the same siRNA; c: \( p < 0.001 \) vs IFN-γ-treated NT & siCtrl, d: \( p < 0.001 \) and e: \( p < 0.05 \) vs IL-1β + INF-γ-treated NT & siCtrl, f: \( p < 0.001 \) and g: \( p < 0.05 \) vs TNF-α + INF-γ-treated NT & siCtrl; ANOVA followed by Student’s \( t \) test with Bonferroni correction.

**Figure 5. PTPN2 inhibition increases IFN-γ-induced STAT1 and STAT3 phosphorylation.**

INS-1E were left untransfected (NT) or transfected with 30 nM of either a control siRNA (siCtrl) or with a pool of siRNAs targeting PTPN2 (siPTPN2). After 2 days of recovery, cells were left untreated or treated with IFN-γ (100 U/ml) for 15 min, 30 min, 1h, 2h, 4h, 8h and 24h. (A) phospho-STAT1, total STAT1, phospho-STAT3, total STAT3, PTPN2 and α-tubulin proteins were evaluated by Western blot. These results are representative of 5 independent experiments. (B-C) Mean optical density measurements of phospho-STAT1 (B) and phospho-STAT3 (C) Western blots corrected for protein loading by α-tubulin. Results are mean ± SEM of 5 independent experiments; ** \( p < 0.01 \) and *** \( p < 0.001 \) vs NT & siCtrl at the same time-point, ANOVA followed by Student’s \( t \) test with Bonferroni correction.

**Figure 6. Double knockdown of PTPN2 and STAT1 protects INS-1E cells from cytokine-induced apoptosis.**

INS-1E cells were left untransfected (NT), or were transfected with 60 nM of a control siRNA (siCtrl), or with 30 nM of either a pool of siRNAs targeting PTPN2 (siPTPN2), or a siRNA targeting STAT1 (siSTAT1), or double transfected with 30 nM of both siPTPN2 and siSTAT1. After 2 days of recovery, cells were left untreated, or treated for 24h with IFN-γ (100 U/ml), IL-1β (10 U/ml) + IFN-γ (100 U/ml) or TNF-α (1000 U/ml) + IFN-γ (100 U/ml) as indicated. (A) Expression of STAT1, PTPN2 and α-tubulin proteins were evaluated by Western blot. The results are representative of 3 independent experiments. (B) Apoptosis was evaluated using HO/PI staining. Results are mean ± SEM of 4 independent experiments; a: \( p < 0.001 \) vs untreated NT or untreated transfected with the same siRNA; b: \( p < 0.001 \) vs IFN-γ-treated NT & siCtrl; c: \( p < 0.001 \) vs IFN-γ-treated siSTAT1 & siPTPN2 + siSTAT1; d: \( p < 0.001 \) vs IL-1β + INF-γ-treated NT & siCtrl; e: \( p < 0.001 \) vs IL-1β + INF-γ-treated siSTAT1 & siPTPN2 + siSTAT1; f: \( p < 0.001 \) vs TNF-α + INF-γ-treated NT & siCtrl; g: \( p < 0.001 \) vs TNF-α + INF-γ-treated siSTAT1 & siPTPN2 + siSTAT1; ANOVA followed by Student’s \( t \) test with Bonferroni correction.
