Inflammasome activation in adipose tissue has been implicated in obesity-associated insulin resistance and type 2 diabetes. However, when and how inflammasome is activated in adipose tissue remains speculative. Here we test the hypothesis that extracellular ATP, a potent stimulator of inflammasome in macrophages via purinergic receptor P2X7, ligand-gated ion channel, 7 (P2X7), may play a role in inflammasome activation in adipose tissue in obesity. Our data show that inflammasome is activated in adipose tissue upon 8-week feeding of 60% high-fat diet (HFD), coinciding with the onset of hyperglycemia and hyperinsulinemia as well as the induction of P2X7 in adipose tissue. Unexpectedly, P2X7-deficient animals on HFD exhibit no changes in metabolic phenotypes, inflammatory responses, or inflammasome activation when compared with the wild-type controls. Similar observations have been obtained in hematopoietic cell–specific P2X7-deficient animals generated by bone marrow transplantation. Thus, we conclude that inflammasome activation in adipose tissue in obesity coincides with the onset of hyperglycemia and hyperinsulinemia but, unexpectedly, is not mediated by the ATP-P2X7 signaling axis. The nature of the inflammasome-activating danger signal(s) in adipose tissue in obesity remains to be characterized.

Obesity is a major health threat in both developing and developed countries and poses a significant risk factor for type II diabetes, arthritis, cardiovascular diseases, and even cancer. The progression of obesity is strongly associated with chronic inflammation in white adipose tissue (WAT) (1–4). Genetic studies in mice and clinical studies in humans have shown that downregulation of the inflammatory response in WAT is associated with improvement of systemic glucose homeostasis and insulin sensitivity (5).

Proinflammatory cytokines such as interleukin-1β and -18 (IL-1β and -18) secreted by adipose tissue have been linked to insulin resistance during obesity (6–9). The maturation of IL-1β and IL-18 requires the activation of inflammasomes, including NLRP1 (Nod-like receptor family, pyrin domain containing 1), NLRP3, NLRC4 (Nod-like receptor family, caspase activation and recruitment domain containing 4), and AIM2 (absent in melanoma 2) inflammasome (10). The most well-studied inflammasome is NLRP3 inflammasome, a multiprotein complex consisting of NLRP3, ASC (apoptosis-associated speck-like protein containing COOH-terminal caspase activation and recruitment domain), and a cysteine protease caspase-1. The activation of inflammasome induces the cleavage of procaspase-1 to active caspase-1, which in turn processes pro–IL-1β and pro–IL-18 to bioactive IL-1β and IL-18 to be released (11). Several recent studies have demonstrated that the NLRP3 inflammasome is important for obesity-associated inflammation and the development of insulin resistance (12–15). Indeed, mice deficient in caspase-1 or NLRP3 were protected against obesity-associated inflammation and insulin resistance with reduced circulating IL-18, reduced IL-1β and effector T cells in adipose tissue, and improved systemic insulin sensitivity (12–15). However, it remains unclear when and how inflammasome is activated in high-fat diet (HFD) feeding.

Studies on the immune system have revealed that the activation of inflammasome, or synthesis, processing, and release of mature IL-1β by macrophages, ex vivo requires two stimuli: first, an inflammatory stimuli, such as lipopolysaccharide (LPS), primes cells to transcribe and synthesize pro–IL-1β, and then a second stimulus, such as ATP, nigericin, or bacterial toxins, is required for optimal inflammasome activation and maximal IL-1β release (10). An outstanding question with regards to inflammasome activation in obesity is what the two activating stimuli are in adipose tissue. Stimuli including ATP, glucose, or lipids such as palmitate and ceramides have been suggested to play a role in inflammasome activation in obese adipose tissue (12,14–16).

However, physiological relevance and importance of these stimuli have not been documented with in vivo studies.

Extracellular ATP is a potent inflammasome-activating signal both in vitro and in vivo in some disease settings such as cancer, graft-versus-host disease, hypersensitivity, and sterile inflammation (17–21). Among the several purinergic receptors capable of ATP sensing (P2X1–7 and P2Y1–2, 4, 11, 12), P2X7 (also known as P2RX7) is unique in its ability to activate inflammasome (22). P2X7 is a cell-surface ion channel receptor activated by a high level of extracellular ATP and subsequently allows rapid efflux of potassium ions to activate inflammasome (17,23–25). In vivo, extracellular ATP can be released from apoptotic and necrotic cells as a “danger signal” to upregulate inflammation in a P2X7–dependent manner (18–21,26), suggesting an interesting mechanism by which dying cells regulate inflammasome activation. Intriguingly, obesity is associated with increased cell death in adipose tissue and the aggregation of macrophages around dead cells, also known as “crown-like structure” (27–30). It has been suggested that adipocyte cell death may contribute to the progression of inflammation in adipose tissue (29,31), although these remains...
controversial (30). How cell death is linked to inflammation or inflammasome activation in obesity remains a mystery.

Here we addressed whether extracellular ATP links obesity, obesity-associated cell death, and inflammasome activation in adipose tissue via its receptor P2X7. Our data show that induction of both P2X7 expression and inflammasome activation in adipose tissue started at 8-week feeding of 60% HFD, coinciding with the onset of hyperglycemia and hyperinsulinemia. However, to our surprise, the ATP-P2X7 signaling axis is dispensable for inflammasome activation in obese adipose tissue.

RESEARCH DESIGN AND METHODS

Mouse models. Wild-type (WT) C57BL/6 (CD\#5.2\%; 000664), B6.129P2-P2rx7tm1Gab (P2X7\(^{−/−}\); 005576), B6.129P2-P2y2tm1Kbb/J (P2Y2\(^{−/−}\); 00132), B6.SJL/Pippa\(^{fl}\)Pept\(^{fl}\)/BoyD (CD45.1; 002014), and B6.129-V3\(^{fl}\)/2 (ob/ob; 006832) mice were purchased from the Jackson Laboratory and bred in our facility. The P2X7\(^{−/−}\) and P2Y2\(^{−/−}\) mice had been back-crossed to the B6 background for 7 and 12 generations, respectively. WAT tissue lysates from 16-week HFD caspase-1\(^{−/−}\) mice were provided by Dr. Rinke Stienstra (Wageningen University).

Metabolic phenotyping. Six-week-old male mice were fed with either 13% LFD or 60% HFD for the indicated period of time from 1 to 20 weeks. For GTT, mice were fasted for 16–18 h followed by an injection of glucose (Sigma) at 1 g/kg body weight (BW). For HOMA, mice were fasted for 5 h followed by an injection of insulin (Sigma) at 36 \(\mu\)g/kg BW. Blood glucose was monitored using One-Touch Ultra (LifeScan) or AlphaTRAK Glucometer (Abbott). Fasting insulin levels were measured after a 4-h fast. Mice were killed by cervical dislocation, and tissues were either fixed for histology or snap frozen in liquid nitrogen for Western blot analyses or for metabolic challenge in vivo. Tissues or cells were lysed in Tris-based lysis buffer by homogenization and IL-1\(\beta\) level was normalized to ribosomal S2 gene in the corresponding sample. ELISA.

RESULTS

Inflammasome activation in WAT coincides with the onset of hyperglycemia and hyperinsulinemia. HFD feeding with 60% calories from fat progressively increased BW, gonadal WAT weight, fasting blood glucose, and insulin levels (Fig. 1A). Upon 8 weeks of feeding of 60% HFD, mice developed mild hyperglycemia and hyperinsulinemia. RT-PCR analysis revealed that components of NLRP3 inflammasome such as Nlrp3, Casp1, Asc, Il1b, and Il18 were expressed at much lower levels in mice injected intraperitoneally with 0.1 mg/mL LPS (L4391; Sigma) for 5 h or in 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map. Interestingly, the Nlrc4 gene was expressed at 3,097 genes that were used to generate the heat map.

Intriguingly, most NLRP3 inflammasome components, including Nlrp3, Casp1, and Asc, were highly responsive to HFD feeding and elevated starting at 6 weeks HFD (Fig. 1C), as were other types of inflammasome sensors such as Nlrp1 and Nlrc4 and Arm2 were expressed at much lower levels (Fig. 1B).

Inflammasome activation in WAT coincides with the onset of hyperglycemia and hyperinsulinemia. HFD feeding with 60% calories from fat progressively increased BW, gonadal WAT weight, fasting blood glucose, and insulin levels (Fig. 1A). Upon 8 weeks of feeding of 60% HFD, mice developed mild hyperglycemia and hyperinsulinemia. RT-PCR analysis revealed that components of NLRP3 inflammasome such as Nlrp3, Casp1, Asc, Il1b, and Il18 were highly expressed in mouse epididymal adipose tissue, whereas other types of inflammasome sensors, such as Nlrp1, Nlrc4, and Arm2, were expressed at much lower levels (Fig. 1B). Furthermore, most NLRP3 inflammasome components including Nlrp3, Casp1, Asc, and Il18 were expressed at comparable levels in both adipocytes and SGCs in WAT, whereas Il1b was predominantly present in the SGC fraction of WAT (Fig. 1C).

Inflammasome activation in WAT coincides with the onset of hyperglycemia and hyperinsulinemia. HFD feeding with 60% calories from fat progressively increased BW, gonadal WAT weight, fasting blood glucose, and insulin levels (Fig. 1A). Upon 8 weeks of feeding of 60% HFD, mice developed mild hyperglycemia and hyperinsulinemia. RT-PCR analysis revealed that components of NLRP3 inflammasome such as Nlrp3, Casp1, Asc, Il1b, and Il18 were highly expressed in mouse epididymal adipose tissue, whereas other types of inflammasome sensors, such as Nlrp1, Nlrc4, and Arm2, were expressed at much lower levels (Fig. 1B). Furthermore, most NLRP3 inflammasome components including Nlrp3, Casp1, Asc, and Il18 were expressed at comparable levels in both adipocytes and SGCs in WAT, whereas Il1b was predominantly present in the SGC fraction of WAT (Fig. 1C).
exhibited a similar expression pattern (Fig. 1D and E). The specificity of the caspase-1 antibody was confirmed using adipose tissue from caspase-1−/− animals (Fig. 1F). Consistently, the IL-1β level in epididymal adipose tissue was significantly increased after 12 weeks, but not 6 weeks, HFD (Fig. 1G). Intriguingly, at 8 weeks, not 6 weeks, HFD, cell death in WAT was significantly increased, as measured by levels of cleaved caspase-3 (Fig. 1H and I), as well as the crown-like structures (Supplementary Fig. 2). Thus, we conclude that inflammasome activation in adipose tissue coincides with increased cell death and the onset of hyperglycemia and hyperinsulinemia.

P2X7 expression in adipose tissue coincides with the activation of inflammasome. Early studies have implicated a significant role of ATP-P2X7 signaling in inflammasome activation in macrophages and dendritic cells and in the clearance of dead cells (18, 21, 26). However, whether P2X7 plays a role in adipose tissue remains unclear. RT-PCR analyses revealed that among all P2X family members P2X1–7, P2X7 was expressed at relatively high levels in both adipocytes and SVCs of mouse epididymal adipose tissue (Fig. 2A).

Both mRNA and protein levels of P2X7 were significantly increased in the WAT of 13-week-old ob/ob mice relative to age-matched WT lean mice (Fig. 2B and C). Similar observation was obtained in the liver but not muscle or pancreas (Fig. 2D). We next asked when the induction of P2X7 occurred in adipose tissue using HFD-feeding mouse models. Intriguingly, induction of P2X7 protein also occurred at 8 weeks HFD feeding (Fig. 2E and F), a pattern strikingly similar to that of inflammasome activation. Preceding the induction of its protein, P2X7 mRNA level was elevated starting at 6 weeks HFD (Fig. 2G). Thus, P2X7 protein is induced in adipose tissue after 8 weeks feeding of 60% HFD, coinciding with the activation of inflammasome and the onset of hyperglycemia and hyperinsulinemia.

FIG. 1. Inflammasome activation in WAT requires 8 weeks HFD feeding. A: Body weight, epididymal WAT weight, insulin levels (following a 4-h fast), and blood glucose (following a 16-h fast) in WT mice on 60% HFD for the indicated time periods from 1 to 24 weeks, compared with age-matched mice on LFD (13% fat); n = 6–12 mice each group. B: RT-PCR analysis of various inflammasome components in purified primary adipocytes, SVCs, epididymal WAT, liver, and peritoneal macrophages (Mac) of WT mice. The exclusive presence of Foxp3, a regulatory T cell–specific marker, in the SVC fraction indicates a clean separation of adipocytes and immune cells in SVCs. L32, a loading control; no RT, negative controls with no reverse transcription. C: Q-PCR analysis of various inflammasome components in epididymal WAT from HFD-fed WT mice for the indicated time periods, compared with 18-week-old WT mice on LFD (0 weeks on HFD); n = 5 mice per group. D: Western blot analysis of procaspase-1 p45 (procasp-1) and cleaved caspase-1 p35 in WAT from HFD-fed WT mice with quantification shown in E. F: Western blot analysis of caspase-1 in WAT from 12- and 29-week HFD-fed WT mice and 16-week HFD-fed caspase-1−/− mice, showing the specificity of anti-caspase-1 antibody. Pos. CON, LPS-ATP–treated macrophages. G: IL-1β concentration measured in WAT of WT mice on 0 or 12 weeks of 60% HFD, compared with age-matched mice on LFD; n = 4–5 mice per group. H: Western blot analysis of procaspase-3 and cleaved caspase-3 p17 and p19 in WAT from HFD-fed WT mice with quantification shown in I. For Western blots, each lane represents an individual animal or sample with HSP90 as a loading control. All experiments were repeated at least twice. Values represent mean ± SEM. *P < 0.05, **P < 0.01, and ***P < 0.001, compared to LFD or 0 weeks HFD controls.
Whole-body P2X7 ablation does not affect metabolic status in both lean and obese mice. We next addressed whether the ATP-P2X7 signaling axis plays a role in metabolic regulation in HFD-induced obesity by placing age- and sex-matched WT mice, n = 5–7 mice per group. C and D: Western blot analysis of P2X7 in epididymal WAT, liver, muscle, and pancreas from 13-week-old WT and ob/ob mice (ob). Spleen from WT mice and WAT/liver from P2X7-/- (KO) mice were included as positive and negative controls, respectively. E: Western blot analysis of P2X7 in epididymal WAT from HFD-fed WT mice with quantification shown in F. G: Q-PCR analysis of P2X7 mRNA levels in epididymal WAT from HFD-fed WT mice, compared with 18-week-old WT mice on LFD (0 weeks on HFD); n = 5 mice per group. HSP90, a loading control. All experiments are representative data from two repeats. Values represent mean ± SEM. *P < 0.05 and **P < 0.01.

Whole-body P2X7 ablation does not affect inflammatory status in obese WAT. Given the known role of P2X7 in ATP-induced inflammasome activation, we next addressed whether the ATP-P2X7 signaling axis is required for inflammasome activation in adipose tissue under LFD and 12 weeks HFD. The loss of P2X7 deficiency had no significant effect on the expression of several key pro- and anti-inflammatory genes that were regulated by HFD (Fig. 4H and Supplementary Fig. 4A), including many inflammatory genes (not shown). Taken together, these data suggest that the ATP-P2X7 signaling axis is dispensable for obesity-associated inflammasome activation in WAT.

In addition to P2X7, several other P2 receptors, including P2X1,-6, and P2Y1,-2, 4, 11, 12 are capable of sensing extracellular ATP but are not associated with inflammasome activation (38). Loss of P2X7 did not lead to compensatory increases of other P2 receptors in adipose tissue (Supplementary Fig. 4B). Among the P2 family members, P2Y2, a G protein–coupled receptor that has been implicated in phagocyte migration in response to extracellular nucleotides released by apoptotic cells (26), is highly expressed in adipose tissue (Supplementary Fig. 4C). To further exclude a possible role of P2Y2 in vivo, we characterized the metabolic phenotypes and inflammatory responses of P2X7-/- and P2Y2-/- (KO) mice upon HFD feeding. B–F: Metabolic phenotypes of 18-week-old male mice upon 12 weeks HFD. Epididymal WAT weight (B), hematoxylin-and-eosin staining of WAT sections comparing to WAT from age-matched WT LFD mice (C), GTT with 1 g glucose/kg BW after a 16-h fast (D), serum insulin level after a 4-h fast (E), and Western blot analysis of phosphorylated (p-S473) and total AKT after a 4-h fast (F). For all, n = 10–29 mice per group. Representative data from two repeats shown. Values represent mean ± SEM.

FIG. 3. Whole-body P2X7 ablation does not affect metabolic status of obese mice. A: Body weight of age-matched wild-type (WT) and P2X7-/- (KO) mice upon HFD feeding. B–F: Metabolic phenotypes of 18-week-old male mice upon 12 weeks HFD. Epididymal WAT weight (B), hematoxylin-and-eosin staining of WAT sections comparing to WAT from age-matched WT LFD mice (C), GTT with 1 g glucose/kg BW after a 16-h fast (D), serum insulin level after a 4-h fast (E), and Western blot analysis of phosphorylated (p-S473) and total AKT after a 4-h fast (F). For all, n = 10–29 mice per group. Representative data from two repeats shown. Values represent mean ± SEM.
status in WAT of P2Y2−/− mice after 15 weeks HFD (Supplementary Fig. 5). We failed to observe any alternations in metabolic phenotypes (Supplementary Fig. 5 A–E), in inflammatory responses (Supplementary Fig. 5 F and G), or inflammasome activation (Supplementary Fig. 5 H) in adipose tissue compared with age-matched WT controls. These results excluded the involvement of another ATP receptor, P2Y2, in inflammasome activation in obese WAT.

P2X7 ablation in hematopoietic cells does not affect inflammatory status in obese WAT. To exclude a possible role of P2X7 in somatic cells, such as pancreatic β-cells (39) and adipocytes (40), that may affect the outcome of inflammasome activation in adipose tissue, we next specifically ablated P2X7 in hematopoietic cells using BMT. Preliminary BMT experiments using congenic CD45.1− and CD45.2− mice showed efficient immune cell reconstitution in SCSs of WAT (Supplementary Fig. 6). Next, lethally irradiated WT mice were reconstituted with bone marrow from P2X7−/− or WT mice. Metabolic phenotypes and inflammasome status were examined after 16 weeks HFD after 4 weeks recovery (Fig. 5A). The loss of P2X7 in hematopoietic cells did not affect BW gain, fat weight, and adipose tissue morphology (Fig. 5B–D). Liver and pancreas tissue morphologies were also comparable between experimental and control cohorts (Supplementary Fig. 7). Systemic glucose tolerance and fasting insulin levels were not affected by hematopoietic-specific P2X7 ablation (Fig. 5E and F). Moreover, mice with P2X7 deficiency in hematopoietic cells exhibited no alterations in inflammasome activity as shown by the protein levels of caspase-1 p45 and p35 (Fig. 6A and B) as well as mRNA levels of three key inflammasome components (Fig. 6C). Additionally, the overall inflammasome level in WAT was not altered, as shown by protein levels of IkB (Fig. 6A) and mRNA levels of various inflammatory genes (Fig. 6D). Thus, these data suggest that hematopoietic P2X7 is not required for inflammasome activation in obese adipose tissue.

DISCUSSION

Previous studies have shown that inflammasome is activated in obese adipose tissue either after 36 weeks 60% HFD or 12 weeks 45% HFD feeding (13,15), and it remains unclear how long it takes for HFD feeding to activate inflammasome in adipose tissue. Here, we report a dramatic activation of inflammasome in adipose tissue starting at 8 weeks feeding
of 60% HFD, coinciding with the onset of hyperglycemia and hyperinsulinemia and with cell death. This is consistent with the general timeline of inflammation during diet-induced obesity, which was reported to be up-regulated at 9 weeks in adipose tissue based on the infiltration of macrophages with 60% HFD and the global induction of inflammatory genes in microarray analysis with 45% HFD (28,41). In parallel with the onset of inflammation, cell death in adipose tissue was elevated at about 4–8 weeks 60% HFD and peaked at about 12 weeks HFD (Fig. 1H and I and Supplementary Fig. 2) (28). These tight correlations among HFD feeding, cell death, and inflammatory response strongly suggest that dying cells in obese adipose tissue may release cell death–mediated “danger signals” to activate inflammasome in situ. However, our data demonstrate that extracellular ATP-P2X7 signaling is not involved in inflammasome activation in obese adipose tissue in vivo. This observation is in line with a recent study showing that adipocyte cell death is not sufficient to drive inflammation (30).

We observed that P2X7, an inflammasome-activating ATP receptor in several disease models (17–21,23,26), was highly induced at 8 weeks HFD, coinciding with the inflammasome activation in obese adipose tissue. In line with our observation, a recent study showed that P2X7 expression is increased in adipose tissue of human patients with metabolic syndrome (42). However, our data demonstrated that, although required for LPS-ATP–induced inflammasome activation both in vitro and in vivo (Fig. 4E and F), P2X7 is dispensable for inflammasome activation in obese adipose tissue in vivo. One possible explanation is that the extent of cell death in adipose tissue during obesity may be much lower than the systems used in previous studies, such as drug-induced tumor cell death, host-versus-graft disease, and sterile inflammasome (12–15). Additionally, ATP may be quickly hydrolyzed in extracellular space (22,43). Therefore, as P2X7 receptor requires a high ATP level to be activated (>5 mM) (Fig. 4E), extracellular ATP in obese adipose tissue may not reach the activation threshold for P2X7 and thus fail to activate inflammasome in vivo. This possibility is supported by a study showing that CD39/−/− mice, which are incapable of hydrolyzing extracellular ATP, exhibit exacerbated insulin resistance (44). Although the inflammatory status was not examined in the CD39/−/− mice, this report suggests that extracellular ATP may have a metabolic effect when it reaches a certain level.

Though our data suggest that extracellular ATP may not be the “danger signal” for inflammasome activation in WAT.
during obesity, it does not exclude the potential importance of cell stress and death in obese adipose tissue during the pathogenesis of obesity. Lipid spillover during adipocyte expansion and death has been linked to macrophage infiltration and obesity-associated inflammation (45). Indeed, several studies using lipodystrophy mouse models suggest that adipocyte cell death is important for macrophage infiltration into adipose tissue (46, 47). Furthermore, both palmitate and ceramides, but not unsaturated oleate, have been reported to activate NLRP3 inflammasome in bone marrow–derived macrophages in vitro (14, 15). As saturated fatty acid has been demonstrated to induce ceramide biosynthesis in vivo (48), it remains to be tested whether palmitate and ceramides activate inflammasome in adipose tissue via the same mechanism. Thus, the function of lipids as inflammasome-activating signals in obese adipose tissue and the underlying molecular mechanism are worth further studies.

Alternatively, inflammasome in obese adipose tissue may be activated by mechanisms unrelated to in situ cell death. A high glucose level has been suggested to induce inflammasome activation. In isolated pancreatic islets, a high glucose level was shown to induce thioredoxin interacting protein (TXNIP) expression and then activate inflammasome, which was not mediated by ATP-P2X7 signaling (12). In another independent study, similar induction of TXNIP and IL-1β by glucose was observed in adipose tissue explants and primary adipocytes (16). These reports indicate that hyperglycemia during obesity may lead to inflammasome activation. Interestingly, we observed that the onset of both hyperglycemia and inflammasome activation in adipose tissue occurred at 8 weeks HFD, whereas 6 weeks HFD feeding was not sufficient. Further studies are needed to show the potential role of high circulating glucose levels in inflammasome activation in adipose tissue in vivo.

To date, four classes of inflammasomes have been shown to activate caspase-1 in vivo, including NLRP3, NLRC4, and AIM2 inflammasome (10). Different classes of inflammasomes may respond to specific environmental cues. For example, the NLRC4 inflammasome is activated by gram-negative bacteria, the AIM2 inflammasome senses cytosolic double-stranded DNA, and the NLRP3 inflammasome responds to a number of pathogen-associated or endogenous danger–associated activators (10). Previous studies on inflammasomes in adipose tissue focused on NLRP3 inflammasome (13, 15). However, the nature of inflammasomes in adipose tissue remains unclear and their cell-type specificity has not been examined. Here, we determined the expression of the four classes of inflammasomes in epididymal adipose tissue and liver by assessing the relative transcript levels of their sensors. Besides NLRP3, our data show that both NLRC4 and NLRC4 were also expressed in adipose tissue and were highly induced after 8 weeks HFD. In contrast, AIM2 expression was very low in adipose tissue. Thus, the role of non-NLRP3 inflammasomes in adipose inflammation in obesity requires further investigation.

Inflammasome activation generates two active caspase-1 subunits, p20 and p10, with enzymatic activities (10). In addition, as first reported by Tschopp and colleagues (94) in a cell-free system, the caspase-1 intermediate product p35 may also serve as an indicator for the activation of caspase-1. Recently, several studies by different groups have used p35 as a marker of inflammasome activation in tissues (13, 18, 35). Indeed, our data show that the p35 band is caspase-1 specific as it disappears in the caspase-1-deficient adipose tissue (Fig. 1F), and more importantly, that the appearance of caspase-1 p35 subunit in WAT under various physiological settings is in line with that of caspase-1 p20 (Fig. 1D and F, Fig. 4A, and Fig. 6A vs. Supplementary Fig. 8). Thus, the caspase-1 p35 fragment, albeit possibly not the active form, may be a bona fide indicator of inflammasome status in WAT.

P2X7 was previously reported to regulate pancreatic β-cell functions by modulating insulin secretion and β-cell mass (39). Upon feeding with high-fat/high-sucrose Surwit diet (58% fat with majority of saturated fat, 26% carbohydrate, and 16% protein, no fiber) for 12 weeks, P2X7−/− mice developed hyperglycemia, severe glucose intolerance, decreased β-cell mass, and impaired β-cell function (39). Such β-cell–associated diabetic phenotype, however, was not observed in our study (Fig. 3 and Supplementary Figs. 3 and 7). The discrepancies may be due to specific diets used in the studies. In addition, the ATP-P2X7 signaling axis has been reported to induce lipolysis and inhibit insulin signaling in adipocytes in vitro by upregulating cyclic AMP levels or inhibiting phosphorylation on insulin receptor substrate and AKT in rat primary adipocytes (40, 49, 50). In contrast, others have reported that insulin signaling was down-regulated by ATP-P2X7 in astrocytes (51, 52). Here in our study, animals with both global and hematopoietic-specific deletion of P2X7 did not exhibit altered systemic insulin sensitivity and adiposity, suggesting a dispensable role of ATP-P2X7 signaling in regulating adipocyte function and insulin sensitivity in vivo.

In conclusion, our study showed that inflammasome is activated concurrently with the development of hyperglycemia and hyperinsulinemia. Unexpectedly, the ATP-P2X7 signaling axis seems not to play a critical role in this process. Further studies are required to identify and characterize the endogenous signal(s) that is responsible for inflammasome activation in adipose tissue during obesity.
