

Glycation and Carboxymethyllysine Levels in Skin Collagen Predict the Risk of Future 10-Year Progression of Diabetic Retinopathy and Nephropathy in the Diabetes Control and Complications Trial and Epidemiology of Diabetes Interventions and Complications Participants With Type 1 Diabetes

Saul Genuth,¹ Wanjie Sun,² Patricia Cleary,² David R. Sell,³ William Dahms,⁴ John Malone,⁵ William Sivitz,⁶ and Vincent M. Monnier,^{3,7} for the DCCT Skin Collagen Ancillary Study Group*

Several mechanistic pathways linking hyperglycemia to diabetes complications, including glycation of proteins and formation of advanced glycation end products (AGEs), have been proposed. We investigated the hypothesis that skin collagen glycation and AGEs predict the risk of progression of microvascular disease. We measured glycation products in the skin collagen of 211 Diabetes Control and Complications Trial (DCCT) volunteers in 1992 who continued to be followed in the Epidemiology of Diabetes Interventions and Complications study for 10 years. We determined whether the earlier measurements of glycated collagen and AGE levels correlated with the risk of progression of retinopathy and nephropathy from the end of the DCCT to 10 years later. In multivariate analyses, the combination of furosine (glycated collagen) and carboxymethyllysine (CML) predicted the progression of retinopathy ($\chi^2 = 59.4$, $P < 0.0001$) and nephropathy ($\chi^2 = 18.2$, $P = 0.0001$), even after adjustment for mean HbA_{1c} (A1C) ($\chi^2 = 32.7$, $P < 0.0001$ for retinopathy) and ($\chi^2 = 12.8$, $P = 0.0016$ for nephropathy). The predictive effect of A1C vanished after adjustment for furosine and CML ($\chi^2 = 0.0002$, $P = 0.987$ for retinopathy and $\chi^2 = 0.0002$, $P = 0.964$ for nephropathy). Furosine explained more of the variation in the 10-year progression of retinopathy and nephropathy than did CML. These results strengthen the

role of glycation of proteins and AGE formation in the pathogenesis of retinopathy and nephropathy. Glycation and subsequent AGE formation may explain the risk of these complications associated with prior A1C and provide a rational basis for the phenomenon of "metabolic memory" in the pathogenesis of these diabetes complications. *Diabetes* 54:3103–3111, 2005

Nonenzymatic glycation of proteins and subsequent formation of advanced glycation end products (AGEs) is one of the pathogenetic mechanisms thought to link hyperglycemia to diabetic retinopathy and nephropathy (1,2). Inhibitors of AGE formation (3–8) and breakers of AGE-protein cross-links (9,10) reduce both microvascular complications in experimental diabetic models. The relationship of long-term intensive control of glycemia and its effect on these complications with indicators of skin collagen glycation (furosine), glycoxidation and AGE formation (pentosidine and carboxymethyllysine [CML]), and cross-linking (acid and pepsin solubility) were previously examined in 215 patients with type 1 diabetes from the Diabetes Control and Complications Trial (DCCT) (11) who underwent a skin biopsy ~1 year before the close of the trial. Compared with conventional treatment, intensive treatment was associated with significantly lower levels of furosine, pentosidine, CML, and relative fluorescence and with higher levels of acid- and pepsin-soluble collagen (11). Age- and duration-adjusted collagen variables were significantly associated with the A1C value closest in time to the biopsy and with mean DCCT A1C. Retinopathy, nephropathy, and neuropathy outcomes as dependent variables were significantly associated with the full set of collagen measurements as independent variables, even after adjustment for A1C levels (11). The early Amadori product of glycation, as well as AGEs, contributed to the cross-sectional associations.

To further test the glycation/AGE hypothesis, we have monitored these subjects for development and progression of complications in the Epidemiology of Diabetes Interventions and Complications (EDIC) study to determine whether skin glycation products could be better

predictors of the future risk of complications than A1C. We now report the relationship of the incidence of retinopathy and nephropathy progression during 10 years of follow-up to the previous levels of skin collagen glycation and AGEs.

RESEARCH DESIGN AND METHODS

A total of 216 subjects (53% of those available in eight DCCT clinics) with type 1 diabetes volunteered to undergo a skin biopsy in 1991–1992. Informed consent was obtained. One hundred twenty-two had originally been assigned to the intensive and 94 to the conventional treatment groups of the DCCT. Of the intensive group subjects, 65 (53%) were from the primary prevention cohort that had no retinopathy or microalbuminuria at the DCCT baseline and 57 (47%) were from the secondary intervention cohort of the DCCT with mild to moderate nonproliferative retinopathy and albumin excretion rates (AERs) <200 mg/24 h (12). Of those in the conventional group, 58 (62%) were from the primary prevention cohort and 36 (38%) were from the secondary prevention cohort. Forty nondiabetic subjects between 20 and 51 years of age served as age-matched control subjects.

During the EDIC study, fundus photographs were performed in the whole cohort at years 4 and 10 and in one-fourth of the cohort in rotation annually. Four-hour timed urine collections for AER were obtained biannually. Of the skin biopsy cohort, four participants died and one became inactive. Of those subjects who had not undergone scatter laser photocoagulation during the DCCT, 184 had fundus photographs at the EDIC study year 10, including 87% of those who had previously been on intensive and 85% of those on conventional therapy. Of 196 subjects who had no microalbuminuria at the DCCT close out, 185 had renal assessments at the EDIC study years 9–10, including 95% of those who had previously been on intensive and 94% of those on conventional therapy.

Assessment of complications. Retinopathy and nephropathy were assessed as during the DCCT (12), and EDIC study outcomes were predefined (13). Progression of retinopathy during the EDIC study was defined as a three-step or greater worsening at any time from the DCCT close out to the EDIC study year 10 on the final Early Treatment of Diabetic Retinopathy Scale of retinopathy severity (12) or initial scatter laser therapy during this interval. Progression of nephropathy was defined as the initial development of microalbuminuria (AER ≥40 mg/24 h), albuminuria (AER ≥300 mg/24 h), or dialysis/transplant at any time between the DCCT close out and the EDIC study years 9 or 10. For both outcomes, the cumulative incidence of events from the DCCT close out was analyzed.

Skin biopsy procedure. A 4-mm skin punch biopsy was taken from the buttocks 10 mm below the iliac crest and immediately rinsed in saline and frozen. Skin collagen levels and methodology for furosine, CML, pentosidine, relative fluorescence at 370/440 nm excitation/emission wavelengths, percent pepsin solubility, and percent acid solubility were previously reported (11). A1C was measured as previously reported (14).

Statistical methods. Covariance adjustment of collagen variables for age and diabetes duration was performed by analysis of residuals from a simple linear model (1). These adjusted skin collagen variables were used in all analyses. Univariate differences between groups with respect to a quantitative variable were assessed using Wilcoxon's rank-sum test for continuous or ordinal variables and χ^2 /Fisher's exact test for categorical variables (15). The Mantel-Haenszel method was used to calculate stratified adjusted odds ratios (ORs) with test-based confidence limits (15). The Breslow Day test was used to test for homogeneity of ORs over strata (15). Multivariate logistic regression analysis was used to assess the effects of covariates on the odds of retinopathic and nephropathic outcomes, and the proportion of variation in risk was assessed using the entropy R^2 (15). Significance of effects of specific covariate blocks, unadjusted as well as adjusted for other covariates, were evaluated using likelihood ratio tests (15). The effects of A1C on outcomes

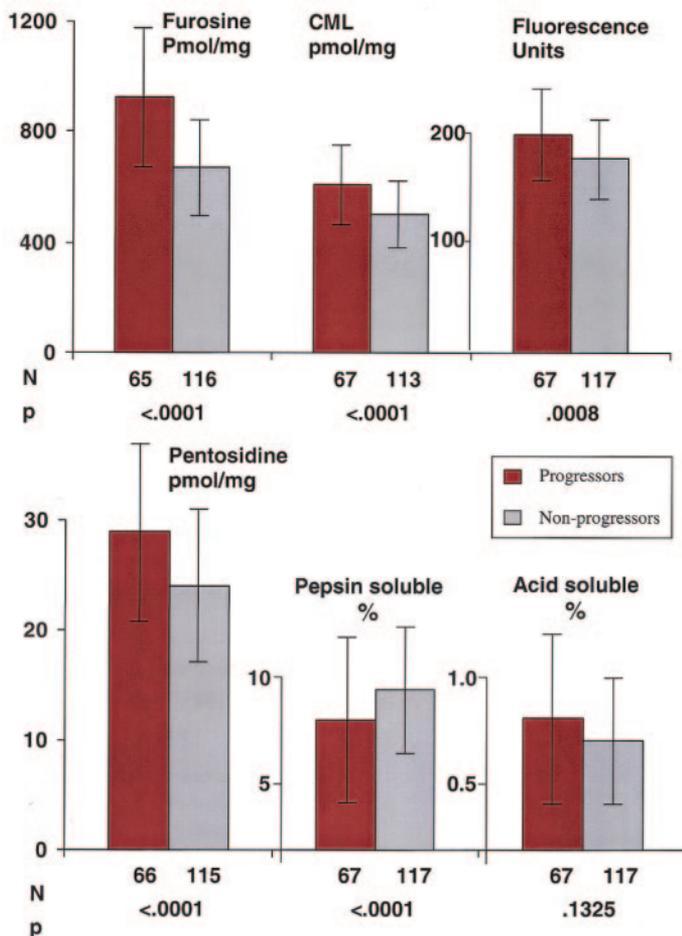

FIG. 1. Distribution of skin collagens by retinopathy progression status. The mean and SD of each skin collagen parameter are compared in those participants whose retinopathy progressed (red bars) three or more steps on the Early Treatment of Diabetic Retinopathy Scale scale and/or required retinal photocoagulation between the end of the DCCT and year 10 of EDIC versus those whose retinopathy did not progress (■). All values are adjusted for age and diabetes duration at the time of the biopsy.

were explored using the mean DCCT A1C, the mean EDIC study A1C, and the time-weighted mean DCCT-EDIC A1C. The DCCT mean A1C is the mean of all quarterly DCCT measurements. The EDIC study mean A1C is the mean of all EDIC study annual measurements. The combined mean A1C is computed as the average of the DCCT and current EDIC study mean values, weighted by the time in DCCT and that in EDIC study. All analyses were performed using SAS software.

RESULTS

Study subject characteristics. The characteristics of the skin biopsy participants with 10-year EDIC study follow-up at the DCCT baseline and the DCCT close-out examinations are shown in Table 1. By comparison, with the nonparticipating DCCT subjects active in the EDIC study at 10 years, the participants at baseline were slightly older, had slightly shorter duration of diabetes, had slightly higher systolic blood pressure, and had slightly lower doses of insulin. The mean A1C and plasma glucose levels were not significantly different. At the DCCT close out, the participants had slightly lower serum triglycerides, a lower percentage of severe nonproliferative retinopathy, and lower AER. Intensive versus conventional treatment group skin biopsy study participants had lower mean A1C levels (7.1 vs. 9.3%, $P < 0.0001$), lower mean plasma glucose levels (150 vs. 231 mg/dl, $P < 0.0001$), and

were more obese (male 120 vs. 113% ideal body weight, $P = 0.017$; female 119 vs. 109% ideal body weight, $P = 0.003$) at the DCCT close out.

Progression of retinopathy. Sixty-seven skin biopsy participants had progression of retinopathy (28 [27%] from the former intensive treatment group and 39 [49%] from the former conventional treatment group, $P = 0.0023$). Figure 1 and Table 2 present comparisons of skin collagen parameters, adjusted for age and diabetes duration in those who did and did not show progression of retinopathy between the DCCT close out and EDIC study year 10. Mean levels of furosine, CML, pentosidine, and fluorescence in those whose retinopathy progressed were significantly higher than in those without retinopathy progression. The mean level of pepsin solubility was significantly lower in the group of progressors, indicating a worse physicochemical collagen abnormality, than in nonprogressors. The acid-soluble levels were not different.

Univariate risk factors for progression of retinopathy are shown in Table 2. Progressors were more likely to have been on the DCCT conventional treatment and to have had higher mean DCCT and EDIC study A1C levels. At the DCCT close out, retinopathy progressors were also more likely to have had microalbuminuria (17.9 vs. 4.3%, $P = 0.0023$) and neuropathy (16.4 vs. 4.3%, $P = 0.0052$). There were no significant differences in blood pressure, lipid levels, or prevalence of overweight.

Multiple logistic regression analysis was performed to determine which skin collagen parameters measured before the close out of the DCCT were predictive of subsequent progression of retinopathy during the EDIC study (Table 3). The dependent retinopathy outcome was predicted by the mean DCCT A1C level ($R^2 = 0.14$, $P < 0.0001$). The entire panel of six collagen parameters was a highly significant and even stronger predictor of retinopathy progression ($R^2 = 0.26$, $P < 0.0001$).

When examined in subblocks, furosine plus CML ($R^2 = 0.25$, $P < 0.0001$) and fluorescence, pentosidine, acid, and pepsin solubility ($R^2 = 0.09$, $P = 0.0002$) were highly significant. However, the variation in risk ascribable to the whole collagen block was explained by furosine and CML alone, and the significance of the other four-collagen parameter subblock was lost when adjusted for furosine and CML ($R^2 = 0.02$, $P = 0.3034$). By contrast, furosine and CML remained significant when adjusted for the other four collagen parameters ($R^2 = 0.19$, $P < 0.0001$). Importantly, the predictive ability of the combination of furosine and CML was independent of the DCCT mean A1C ($R^2 = 0.14$, $P < 0.0001$); however, the predictive value of the DCCT mean A1C was lost after adjusting for furosine and CML ($R^2 = 0.0000$, $P = 0.9874$). Likewise, the predictive ability of furosine and CML was independent of the EDIC study mean A1C ($R^2 = 0.19$, $P < 0.0001$), but that of the EDIC study mean A1C remained significant after adjustment for furosine and CML ($R^2 = 0.11$, $P < 0.0001$) because its influence was closer in time to the outcome and followed that of the glycation products.

When originally measured, furosine and CML each individually correlated with the preceding mean DCCT A1C (11). Therefore, it is noteworthy that furosine alone predicted retinopathy worsening ($R^2 = 0.22$, $P < 0.0001$) and, after ($R^2 = 0.09$, $P < 0.0001$) adjustment, for the DCCT mean A1C. Similarly, the effect of CML alone was significant even with adjustment for the DCCT mean A1C, but the magnitude of the effect was less than that of furosine alone. Furosine and CML both predicted the risk of

retinopathy progression over the 10 years of the EDIC study, independent of the mean A1C. Mean EDIC study A1C remained a significant predictor of retinopathy, adjusted for either furosine or CML, whereas the mean DCCT A1C effect vanished after adjustment for furosine but remained significant after adjustment for CML. For each 1-SD increase in furosine or CML, the ORs for progression of retinopathy were 3.52 (95% CI 2.32–5.34) ($P < 0.0001$) and 2.45 (1.68–3.57) ($P < 0.0001$), respectively.

Figure 2 further illustrates the predictive ability of furosine and the DCCT mean A1C on retinopathy progression. The risk of retinopathy progression in the upper quartile of furosine (>Q3) is compared with the progression in the lower three quartiles of furosine (<Q3). The comparison was first made within the upper quartile of A1C (OR 10.1 [95% CI 1.8–57.9], $P = 0.0038$) and then in the lower three quartiles of A1C (3.0 [0.8–10.9], $P = 0.0890$). Both comparisons show greater risk in the upper

quartile than the lower three quartiles of furosine, though the second comparison was not significant due to the smaller number of events in the lower three quartiles of A1C. When stratified by A1C, the overall OR of retinopathy progression for furosine >Q3 vs. <Q3 remains significant (4.8 [1.8–13.2], $P = 0.0014$, homogeneity of OR across strata tested by Breslow-Day test: $P = 0.2636$). By contrast, the overall OR for the DCCT mean A1C (>Q3 vs. <Q3) stratified by furosine is not significant anymore (1.6 [0.6–4.5], $P = 0.3664$, Breslow-Day P value = 0.2643), even though the DCCT mean A1C was a highly significant predictor of retinopathy progression by itself (4.8 [2.4–9.9], $P < 0.0001$). These results further demonstrated the dominance of furosine over A1C as a risk factor for retinopathy progression.

Progression of nephropathy. A total of 34 participants had progression of nephropathy (18 [17%] from the former intensive group and 16 [20%] from the former conventional

Dependent variable: three or more-step progression of retinopathy on the Early Treatment of Diabetic Retinopathy Scale or scatter laser therapy from DCCT close out through EDIC study year 10. As defined in the statistical methods section, χ^2 and *P* values are from likelihood ratio test, and *R*² is entropy *R*².

group, *P* = 0.5698). Figure 3 and Table 2 present comparisons of the mean skin collagen parameters adjusted for age and diabetes duration in those subjects who did and did not develop nephropathy up to EDIC study years 9–10. The results were comparable with those for retinopathy. Mean values of furosine, CML, pentosidine, and fluorescence were significantly higher in the nephropathy progressors, and the mean value of pepsin solubility but not acid solubility was significantly lower in the progressors.

Univariate risk factors for progression of nephropathy in the skin biopsy cohort are shown in Table 2. The mean A1C level during the DCCT and during the EDIC study were both higher in progressors. The prevalence of hypertension was significantly higher (25.0 vs. 8.6%, *P* = 0.0281), but mean blood pressure was higher with only borderline statistical significance (92.7 vs. 88.2, *P* = 0.0555) at close out of the DCCT in the progressors. LDL cholesterol and AER were also significantly higher at that time.

In multivariate logistic regression analyses (Table 4), nephropathy progression was predicted by the DCCT mean A1C (*R*² = 0.06, *P* = 0.0012), more strongly by the EDIC study mean A1C (*R*² = 0.19, *P* < 0.0001), and by the log of the DCCT close-out AER (*R*² = 0.08, *P* = 0.0002). The pattern of prediction by collagen parameters was similar to that of the retinopathy outcomes. The furosine and CML combination was again a significant predictor of progression of nephropathy, explaining most of the variation in risk attributable to the whole panel of collagen parameters (*R*² = 0.11, *P* = 0.0001) and independent of the mean DCCT A1C and DCCT close-out AER (*R*² = 0.08, *P* = 0.0014). By contrast, DCCT A1C was no longer predictive of nephropathy progression when adjusted for the combination of furosine and CML (*R*² = 0.0000, *P* = 0.9643). The remaining four-collagen parameter subblock was not significantly predictive of nephropathy progression after adjustment for furosine and CML. The furosine and CML combination was a significant nephropathy predictor, independent of the EDIC study mean A1C, but the latter also remained significant after adjustment for the two collagen parameters.

Furosine alone (*R*² = 0.08, *P* = 0.0002) and CML alone (*R*² = 0.06, *P* = 0.0014) each predicted development of nephropathy, independently of the mean DCCT A1C (furosine *R*² = 0.04, *P* = 0.0079 and CML *R*² = 0.04, *P* = 0.0123). Furosine and CML each predicted nephropathy after adjustment for mean EDIC study A1C. However, whereas the mean DCCT A1C lost its significance when adjusted for furosine and CML, mean EDIC study A1C did not. For each 1-SD increase of furosine or CML, the ORs for progression of nephropathy were 2.03 (95% CI 1.38–2.98, *P* = 0.0003) and 1.81 (1.24–2.64, *P* = 0.002), respectively.

DISCUSSION

The present study provides the first demonstration, to our knowledge, that skin levels of glycated collagen (furosine), an Amadori product of glucose, and of a specific AGE, namely CML, can predict the subsequent progression of diabetic microvascular complications in people with type 1 diabetes, even for as long as the ensuing 10 years. The strength and consistency of the association in multivariate analyses and the biological gradient it exhibits support the inference that a causal relationship of glycation and AGE formation with the risks of retinopathy and nephropathy may exist. While levels of glycation products could not be measured in the retina or the kidney of the DCCT subjects, previous studies have revealed correlations among various adducts in diabetic human tissues (16).

The independence of the predictive association of skin collagen glycation and AGE formation with progression of complications from frequently measured A1C both before and after the skin biopsy suggests that this relationship is not just a reflection of chronically elevated plasma glucose levels. This is an important distinction because hyperglycemia clearly drives glycation of hemoglobin as well as glycation of collagen and AGE formation. Indeed, skin collagen furosine and AGEs correlate well with preceding A1C (11). However, when preceding chronic hyperglycemia (expressed as the mean DCCT A1C) is adjusted for the furosine and CML levels it led to, its own strong predictive power can be substituted for by the skin collagen glycation product and the AGE. By contrast, subsequent hyperglycemia (expressed as the mean EDIC study A1C) retained its predictive power after adjustment for the preceding

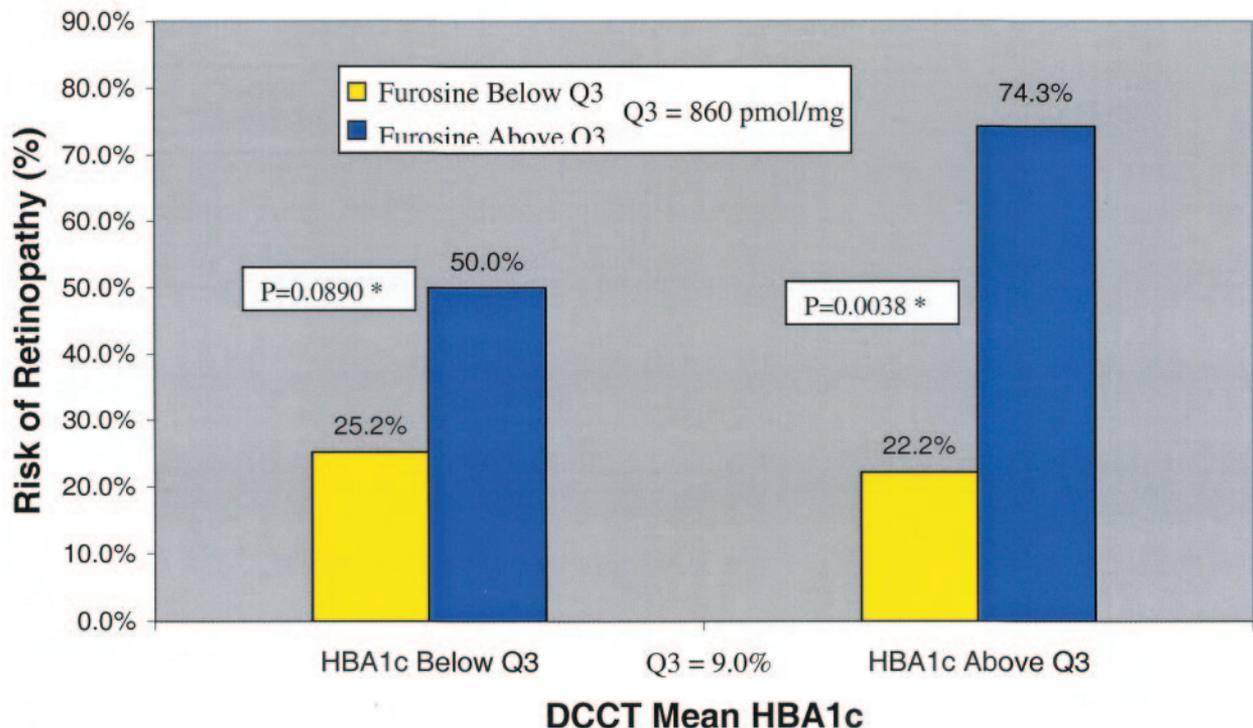

FIG. 2. Risk of retinopathy progression by DCCT mean A1C and furosine. Shown is the risk of progression of retinopathy in the upper quartile of skin collagen furosine (>Q3) (blue bars) compared with the progression in the lower three quartiles of furosine (<Q3) (yellow bars). The comparison is made in the upper (>Q3) and lower three (<Q3) quartiles of A1C separately. *P value is from a between-group furosine (>Q3 vs. <Q3) comparison within each A1C (HBA1c) strata using the χ^2 test. The greatest risk of progression occurs when both furosine and A1C are >Q3, but the dominance of furosine over A1C as a risk factor is evident.

skin collagen levels of furosine and CML. Most previous studies (17–19) have shown only cross-sectional associations between AGEs and complications in various cohorts of type 1 and type 2 diabetic individuals and have not taken into account the coexisting correlations between AGEs and A1C. In our own previous cross-sectional study, the associations between complications and AGEs were largely independent of A1C (11). Another study (20) reported an inverse association between CML concentrations in protein from memory T-cells and years of retinopathy-free diabetes that was also independent of A1C.

The possible pathogenetic significance of glucose bound to collagen (furosine) as a predictor of complications qualitatively parallels that of glucose bound to hemoglobin (A1C) as a predictor, since both are simply glycosylated molecules and not AGEs. However, as illustrated in Fig. 2, a high furosine level (>Q3) with a low level of A1C (<Q3) was associated with a higher prevalence of progression of retinopathy of 50% than was a high level of A1C (>Q3) with a low level of furosine (<Q3), where the prevalence was only 22%. The level of furosine in skin collagen correlated strongly with the A1C concentration measured for up to 1 year before the biopsy (11). Nonetheless, furosine was an independent predictor, even after adjustment for A1C (Table 3) and at both the highest and lowest levels of A1C (Fig. 2). Furosine also contributed more to the variation in retinopathy than did A1C and was a stronger predictor (Table 3). This at least suggests that the proclivity to be glycosylated of collagen, or other extracellular or intracellular proteins for which collagen might only be a marker, is a factor, in addition to and independent of the actual ambient glucose level, in the pathogenesis of micro-

vascular complications. Glycation of mesangium, in fact, has been proposed as one mediator in the development of diabetic nephropathy (21). Furthermore, ACE inhibitors (22) and pyridoxamine (23,24) reduce the development of diabetic nephropathy, concurrent with a decreased accumulation of AGEs resulting from glycation.

Nonetheless, it must be noted that there are other reasons why A1C and furosine could have different relations to average glycemic levels and different predictive powers for complications. For example, interindividual differences in glycation of hemoglobin at similar blood glucose levels that are not explained by differences in erythrocyte survival have been reported (25). Moreover, A1C may be partially enzymatically deglycosylated (26–28), while no such reaction has thus far been discovered for furosine incorporated within extracellular collagen. The role of glycation may also be questioned on the grounds that high-dose thiamine and benfotiamine can prevent diabetic nephropathy without decreasing A1C or furosine levels (29).

Although CML is in part a downstream product of furosine, thus arising from hyperglycemia, CML is also a product of lipid peroxidation and glycooxidation (30) and of metal and peroxynitrite catalyzed oxidative stress (31); overproduction of reactive oxygen species in mitochondria exposed to excessive cellular flux of glucose contributes to CML formation (32,33). However, other products of oxidative stress such as ortho-tyrosine and methionine sulfoxide have not been elevated in skin collagen from diabetic humans, even though CML was present in excess (34). CML, whatever its origin, and Amadori products of glycation are found in increased amounts in the retina and kidneys of diabetic animals (35–37), along with other

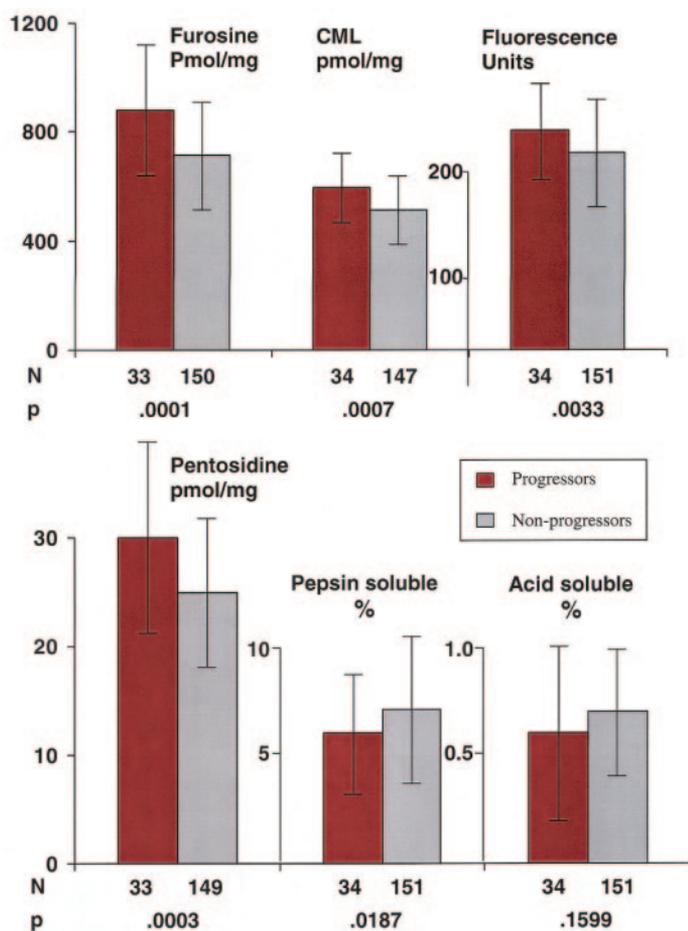

FIG. 3. Distribution of skin collagens by nephropathy progression status. The mean and SD of each skin collagen parameter are compared in those participants who developed microalbuminuria or worse (red bars) between the end of the DCCT and EDIC year 9–10 versus those who did not develop microalbuminuria (□). All values are adjusted for age and diabetes duration at the time of the biopsy.

damaging AGEs, and in human diabetic retinopathy (35) and nephropathy (38). CML has been found to have detrimental biological effects by activating the RAGE receptor in one study (39) but not another (40), where endotoxin-free ribose-BSA was the ligand used. CML may perpetuate a vicious proinflammatory cycle and stimulate extracellular matrix production and thereby contribute to progression of nephropathy (40–42). Small increases in glomerular protein CML were partially reversed in the course of benfotiamine therapy that prevented diabetic nephropathy in rats (29). The present findings support the relevance of such CML observations in animals to human type 1 diabetes.

The multivariate modeling results consistently suggest that variation in the risks of progression of both retinopathy and nephropathy attributable to preceding glycemia can be partly explained by the skin collagen levels of furosine and CML. A single pathway or similar pathways could lead to both complications. However, furosine and CML account for only a portion of the variance in retinopathy and nephropathy. Alternatively, it is possible that CML and other AGEs in collagen may be long-lived biomarkers of damage produced by other molecular mechanisms in the patients' past, for example stemming from methylglyoxal, which is also present in elevated levels in diabetic tissues (43). Glycation of extracellular collagen

Dependent variable: development of microalbuminuria or worse from DCCT close out through EDIC study year 10. As defined in the statistical methods section, χ^2 and P values are from likelihood ratio test, and R^2 is entropy R^2 .

may also only be a marker for glycation of intracellular proteins and other macromolecules, with harmful cellular consequences. Moreover, glycation and AGE formation (1,2) are not the sole mechanisms of hyperglycemic damage that have been uncovered (44). Other pathways demonstrated in diabetic animals (1,2,32) need to be further studied in humans. The roles of protein kinase C and aldose reductase activation, hexosamine production, insufficient activity of superoxide dismutase, and increased oxidative stress should be explored with emphasis on the abilities of unique biomarkers of each pathway to predict the development and progression of complications over time. Nonetheless, the present results reaffirm the possi-

bility that developing safe drugs that block glycation (5) or break AGE cross-links (45) or that interfere with a damaging pathway that includes CML as a component may have the potential to reduce the development or progression of both retinopathy and nephropathy. In a randomized clinical trial (46), aminoguanidine, an inhibitor of AGE formation, reduced urinary protein excretion and progression of retinopathy but failed to benefit significantly the primary outcome measure of a doubling of serum creatinine.

The DCCT/EDIC study has clearly shown that prior intensive treatment and lower mean A1C during the DCCT period continue to exert a beneficial effect during the EDIC study on retinopathy for at least 7 years (47) and on nephropathy for at least 7–8 years (48). This beneficial effect persists even though the large differences in A1C between the two formerly randomized treatment groups dissipated during the EDIC study (48). Our findings suggest a plausible mechanism for this phenomenon that we call “metabolic memory.” A damaging effect of AGE (e.g., CML) formation in long-lived protein molecules such as collagen, which has a half-life of 15 years in normal human skin (49), could explain why the beneficial effects of intensive therapy and the deleterious effects of conventional therapy persist. On the other hand, this would not apply to simple glycated collagen (furosine), which has a much shorter half-life. Thus, furosine in collagen may be reporting preceding periods of hyperglycemic damage without necessarily mediating that damage itself.

Certain limitations of these results should be noted. Skin collagen parameter measurements were available from only a single biopsy at a single point in time. We have thus far not been able to determine the variability in these levels. We do not know whether skin collagen changes in humans quantitatively represent similar changes in their retina and kidneys, although diabetic animal studies (35,36) demonstrate a wide tissue distribution of AGEs. Finally, whether the observations in this research cohort are generalizable to the whole population with type 1 diabetes is unknown.

In summary, measurements of skin collagen furosine (glycated collagen) and AGEs, especially CML, predict the risk of future progression of retinopathy over 10 years and nephropathy over 9–10 years in individuals with type 1 diabetes. Their effects are independent of the preceding A1C levels or those later present during progression of these complications. Thus, they may have effects downstream from hyperglycemia. These human data strengthen the hypothesis that glycation and AGE formation may play pathogenetic roles in the development of these complications.

ACKNOWLEDGMENTS

This study was supported by a grant from the American Diabetes Association and grants and a contract from the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK UO1 AM 30628), the National Institute of Aging (AG 05601 and AG 18629), National Institutes of Health (DK 57733), and the participating Clinical Research Centers at University Hospitals of Cleveland (M01 RR00080), MA General Hospital (M01 RR01066), Albert Einstein College of Medicine (RR12248), Mayo Clinic (RR01066), University of California San Diego (RR00827), University of Iowa (RR00059), and Washington University (RR00036).

We thank Dr. David Nathan and Dr. John Lachin for

their critical review of the manuscript and Theresa Bongorno for its skillful preparation.
